Received 6 April 2004; revised 19 July 2004; accepted 27 July 2004; published 24 August 2004.

Continuous GPS and seismic data from northern California show that slow earthquakes periodically rupture the Gorda-North America plate interface within southern Cascadia. On average, these creep events have occurred every 10.9 ± 1.2 months since at least 1998. Appearing as week-long GPS extensional transients that reverse secular forearc contraction, the data show a recurrence interval 22% shorter than slow events recognized to the north. Seismic tremor here accompanies the GPS reversals, correlated across as many as 5 northern California seismometers. Tremor occurs sporadically throughout the year, but increases in duration and intensity by a factor of about 10 simultaneous with the GPS reversals. Beneath west-central Oregon, three reversals are also apparent, but more stations are needed to confirm sporadic slip on the plate interface here. Together, these measurements suggest that slow earthquakes likely occur throughout the Cascadia subduction zone and add further evidence for the role of fault-fluid migration in controlling transient slow-slip events here. Index Terms: 1206 Geodesy and Gravity: Crustal movements—interplate (8155); 1243 Geodesy and Gravity: Space geodetic surveys; 7230 Seismology: Seismicity and seismotectonics. 1. Introduction

Slow faulting events recently recognized along convergent margins globally are now understood to constitute a fundamental mode of moment release that both trigger and precipitate events, also called slow earthquakes, silent earthquakes, or slow slip or that instrument density is insufficient outside this region for confident detection. Since slow earthquakes may modulate seismogenic rupture either by reducing the size of a future earthquake, delaying its recurrence, or acting as a trigger, along-strike variability in the existence of slow faulting yields important clues about partitioning, particularly seismogenic segmentation, of the Cascadia subduction zone. In this report we present continuous GPS and seismic data from northern California and Oregon that indicates periodic slow earthquakes occur throughout Cascadia, and with quite variable recurrence rates.

2. GPS Data

Continuous GPS data from the Pacific Northwest Geodetic Array and the Bay Area Regional Deformation Array [Miller et al., 2001; Murray et al., 1998] were processed with the Gipsy-Oasis II software [Lichten and Border, 1987] (Figure 1). Precise point positioning and precise orbits and clocks were used to analyze the phase data with ambiguity resolution applied [Heilin et al., 1992; Zumberge et al., 1997]. Daily solutions for station positions and corresponding matrices of the covariance among the three position components were determined within the International Terrestrial Reference Frame (ITRF 2000) [Altamimi et al., 2002] using daily frame data products provided by the International Geodynamics Service [Zumberge et al., 1997]. A regional stabilization was subsequently applied to each daily position, using a reference set of 42 stations from the North America plate region; 23 of these are concentrated in the Pacific Northwest, the remainder are distributed on the stable plate interior or in other regional networks in western North America. Of the 42 stations, 33 have published positions and velocities in ITRF 2000. This stabilization transformation minimizes network-wide position discrepancies, or common-mode errors. Final time series were simultaneously detrended and corrected for known artifacts that include offsets due to hardware upgrades, earthquakes, and annual and semi-annual sinusoidal signals introduced by mismodeled tropospheric delays and other seasonal effects [Blewitt and Lavallée, 2002; Nikolaidis, 2002].

3. Seismic Tremor Data

Continuous horizontal component 100-hz seismic data from Guralp 40T’s and 20-hz seismic data from a combination of both STS-1’s and STS-2’s spanning four years from 2000 through 2003 were downloaded from the Northern California Seismic Network (Figure 1). Eight stations are available with minor outages that together span northernmost California, with average spacing of 136 km. Four stations lie within 150 km of the trench, two of which (YBH and WDC) are among the quietest of stations in northern California based on our examination of four years.
of continuous seismic data from all available stations. Four additional stations lie sufficiently west and south of where tremor is expected to be visible and can be used to assess background noise when picking tremor. Due to the distances between instruments, signals correlated across stations must have their genesis in deep-earth processes and cannot be attributed to anthropogenic, meteorologic or other local noise sources. Tremor signals are readily correlated by eye (Figure 2), and their spectra show predominant frequencies in the 1–5 Hz band, similar to that reported in Japan and northern Cascadia [Obara, 2002; Rogers and Dragert, 2003]. All seismic data in this study were band-passed between 1 and 5 Hz frequencies and gain-normalized to enhance tremor identification. The data record a multitude of signals that include local non-tectonic noise, teleseismic and local earthquakes; tremor signals are distinguished by waveform and coda correlation across adjacent stations. However, due to the emergent nature of the signal [Rogers and Dragert, 2003], and the lack of accurately identifiable phases, constraining event onset time with the precision required to determine source depth and location becomes highly assumption-dependent and was not performed in this study.

Identification of tremor entailed plotting all gain-removed, horizontal seismic traces in spatial and temporal proximity, similar to historical drum recordings. Tremor was then identified as signals correlated both temporally and spatially across at least three stations. Periods during which no correlated tremor is evident have background seismic velocities typically less than 0.07 micrometers per second. We therefore summed the rate of visibly correlated tremor whose maximum velocities exceed 0.5 micrometers per second, or roughly 10-times background noise. Figure 2 shows a typical example, approximately 21 minutes of tremor recorded on 5 seismic stations. This window was taken from a much longer burst recorded on 12/10/2002, two days after the onset of transient westward movement of the GPS station YBHB that began on 12/08/2002. During the time of this GPS reversal, correlated tremor activity increased to approximately 90 hours per week.

4. Northern California and Central Oregon Transients

[6] Purely from the standpoint of deformation, westerly resets at YBHB are expected for slow earthquakes along the deeper Gorda-North American plate interface. Surface deformation from such events results from a sum of contraction from shallow plate locking and extension from the slow faulting itself. Since secular deformation in
slow earthquakes at ALBH. Dragert [2003]. Solid black lines denote times of known 2002.93 and 2003.81. The amplitudes are similar to those particularly westerly jumps of up to 4 mm occurring at northern California show similar characteristics as ALBH, identified, are shown in Figure 3c. Residuals from YBHB in strating periodic resets. For comparison, longitude resets Figure 3a shows GPS residuals at station YBHB demon- strating periodic resets. For comparison, longitude resets should be and are opposite to the direction of subduction. By contrast, time series from nearby stations TRND, CME1, PTSG and MDMT (Figure 1) show no such resets, indicating the observed resets are not reference-frame artifacts.

[7] Transient slow faulting in northern Cascadia was recognized primarily from deformation reversals correlated across nearby continuous GPS stations, but the GPS instrument density in northern California is currently insufficient for any similar correlation. The nearest continuous GPS station to YBHB lies on the coast (PTSG) at a distance of 120 km; by comparison, there are seven stations within 60 km of each other in the northern Puget basin. Nonetheless, Figure 3a shows the longitude component of YBHB overlying a histogram of hours of correlated tremor from a nearby seismic station (YBH). The remarkable correlation between tremor rate and GPS deformation reversals is readily apparent and confirms that slow earthquakes occur beneath northern California. Although background tremor here is detected during many weeks of the year when no GPS reversals are evident, the rate of tremor increases by an order of magnitude during GPS reversals.

[8] Coastal Oregon also shows preliminary evidence of westerly resets at station NEWP, located in Newport, Oregon. These reversals have similar amplitudes to those at YBHB and northern Puget stations, but do not yet show periodic behavior. NEWP shows three resets in longitude, at 2000.52, 2001.98 and 2003.99. These offsets are not observed at the GPS station CORV located 60 km inland in Corvallis, Oregon. The absence of offsets at station CORV is consistent with relatively narrow, offshore locked and transition zones at this latitude, also suggested from vertical deformation rates [Mitchell et al., 1994]. Thus, CORV may lie well east of the down-dip edge of the transition zone where slow earthquakes occur. At the present time, however, the dearth of GPS or seismic data close to NEWP precludes determination of spatially coherent events.

5. Discussion

[9] The northern California data demonstrate that slow Cascadia earthquakes are not confined to the structural bight in the Juan de Fuca plate beneath the northern Puget Basin, and argue that they occur throughout Cascadia and many other subduction zones. More importantly, these results follow Obara [2002] and Rogers and Dragert [2003] in linking seismic tremor and slow faulting to one underlying cause, most likely fault fluid transport [Melbourne and Webb, 2003]. Analysis of tremor alone for source processes that might constrain such transport is complex, since the lack of discernible phases prohibits discrimination between path and source contributions to tremor coda. For example, delta-function sources, propagated through complex crustal media, have been shown to cause harmonic volcano tremor originally attributed to resonance at the source [Chouet et al., 1987; Kedar et al., 1998; Koyanagi et al., 1987]. Moreover, if Cascadia tremor does indeed result from a harmonic source at depth, a host of distinct driving mechanisms could produce source resonance and identical surface observations, again obfuscating the underlying physics [Chouet et al., 1987; Koyanagi et al., 1987].
If both tremor and slow slip are manifestations of hydraulic transport resonating and unclamping fault walls that sandwich pore fluids, an important next step will be to implement experiments that can constrain near-field (static), non-double couple components of moment release. These, in turn, will likely be of great use in constraining slow earthquake physics at a resolution higher than that afforded by either GPS or tremor.
